Abstract. The geographic distribution of the species of *Datura* in Mexico was analyzed using numerical analysis of natural populations documented by herbarium specimens. A map of Mexico was divided into 239, 1° x 1° squares (latitude and longitude) which were used as sampling geographical units and in which the presence or absence of each species of *Datura* was recorded. Multivariate procedures were applied: a), TWINSpan classification to define *Datura*'s main distribution areas; b), Detrended Correspondence Analysis (DCA) to define *Datura*'s main distribution gradients, and c), Canonical Correspondence Analysis (CCA) to relate distribution patterns with geographical and climatic factors. Species of *Datura* were found in 69% (165) of the squares. TWINSpan defined 14 groups which, when associated with Mexico's biogeographic provinces, were concentrated in the northwestern Mexican provinces as well as in the Altiplano Norte and Altiplano Sur and the Sierra Madre Occidental. DCA indicated that *Datura*'s main distribution patterns are explained by 3 principal gradients: altitude, humidity, and latitude. The CCA identified longitude, precipitation of the driest quarter, altitude, and average temperature of the warmest quarter as the most important variables affecting *Datura*'s distribution patterns. The Depresión del Balsas region of central Mexico is the area with greatest species richness of *Datura*.

Key words: clustering, *Datura*, geographic distribution, Mexico, ordination, biogeographic provinces.

Resumen. Se analizó la distribución geográfica de las especies de *Datura* en México mediante análisis numérico de poblaciones naturales documentadas con ejemplares de herbario. Un mapa de México fue dividido en 239 cuadros de 1° x 1° (latitud y longitud), los cuales se usaron como unidades geográficas de muestreo, y en ellos se registró la presencia o ausencia de cada especie de *Datura*. Se aplicaron procedimientos estadísticos multivariados: a), clasificación por TWINSpan para definir las principales áreas de distribución de *Datura*; b), análisis de correspondencia rectificadas (ACR) para definir los principales gradientes en la distribución de *Datura* y c), análisis de correspondencia canónica (ACC) para relacionar los patrones de distribución con factores geográficos y climáticos. Las especies de *Datura* se localizaron en el 69 % (165) de los cuadros. TWINSpan definió 14 grupos, los cuales, cuando se relacionaron con las provincias biogeográficas mexicanas, estuvieron concentrados en provincias del noroeste de México así como en el Altiplano Norte, Altiplano Sur y la sierra Madre Occidental. El ACR indicó que los patrones de distribución de *Datura* son explicados por 3 gradientes principales: altitud, humedad y latitud. El ACC definió a la longitud, precipitación del trimestre más seco, altitud y temperatura media del trimestre más cálido como las variables más importantes relacionadas con los patrones de distribución de *Datura*. La región de la depresión del Balsas es el área con la mayor riqueza de especies de *Datura*.

Palabras clave: agrupamiento, *Datura*, distribución geográfica, México, ordenación, provincias fisiográficas.

Introduction

The genus *Datura* L. includes 14 species (Hammer et al., 1983; Jiao et al., 2002): *D. stramonium* L., *D. quercifolia* Kunth and *D. ferox* L. of section *Datura*; *D. discolor* Bernhardt, *D. inoxia* Miller, *D. kymatocarpa* A.S. Barclay, *D. lanosa* A.S. Barclay ex Bye, *D. metel* L., *D. pruinosa* Greenman, *D. reburra* A.S. Barclay, *D. wrightii* Regel,

D. leichhardtii F. Mueller ex Bentham, and *D. velutinosa* Fuentes of section *Dutra* Bernhardt; and *D. ceratocaula* Ortega of section *Ceratocaulis* Bernhardt. Only *D. ferox*, *D. leichhardtii*, and *D. velutinosa* are unknown in Mexico under natural conditions. Based upon phytogeographic evidence and historical documents, Symon and Haegi (1991) consider all the species of *Datura* to be native to America where Mexico is an important center of diversity of the genus. Europeans introduced such now cosmopolitan taxa as *D. stramonium*, *D. inoxia*, and *D. metel* to other parts of the world (Symon and Haegi, 1991).

The natural (non-anthropogenic) geographic distribution of species of *Datura* suggests that most of the species are endemic to MegaMexico 3 as defined by Rzedowski (1993) which includes the Mexican territory plus adjacent areas in southwestern USA and northern Central America. Given that the majority of species of *Datura* are native to Mexico and southwestern USA, Barclay (1959) indicated that Mexico is the center of diversity and distribution of the genus and, consequently, the center of evolution and radiation. The extra-Mexican outliers have less diverse morphologies and are similar to some of the species found in Mexico. The majority of the species are adapted to xeric conditions of Mexico to which the species evolved in the region. The other taxa are thought to have migrated to (and diversified in) similar zones in southwestern South America, Australia and China. Within its natural geographic range, the Rio Balsas Depression has been considered the actual center of diversity of the genus.

Phytogeographic studies are important in the analysis and explanation of the distribution patterns of the species because they help understand past and present distribution changes (Cox and Moore, 1993) and can identify floristic areas (McLaughlin, 1994). The only study on *Datura*'s geography was conducted by Ewan (1944) who using leaf shapes of "*Datura meteloides* DC. ex Dunal" attempted a phytogeographic analysis to identify the original center of distribution of this complex in Mexico and southwestern USA. Although the variants in the leaf shapes at the periphery of distribution represent different taxa than are recognized today, Ewan considered the central populations in northern Mexico to coincide with the center of origin of this complex of related species. There are, however, no studies of *Datura* that include a complete phytogeographic analysis of the species found in Mexico and their relationships to environmental factors.

Many phytogeographic analyses include descriptive methods along with distribution maps, but quantitative methods that start with a record of taxa in geographic units have also been used (McLaughlin, 1994). Thus, Jardine (1972) emphasized the importance in phytogeography of using numerical methods that objectively define the distribution of taxa, adding that ordination methods indicate the distribution tendencies of the species with respect to range and direction. Examples of phytogeographic studies with multivariate methods are those by Kohlman and Sánchez (1984) for *Bursera* Jacq. ex L., Martínez (1995) for wild bean (*Phaseolus* L.) taxa, Myklestad and Birks (1993) for *Salix* L., Francisco-Ortega et al. (1994) for *Chamaecytisus proliferus* (L.Fil.) Link, and Gómez-González et al. (2004) for the tribe *Cytiseae* (Fabaceae).

No quantitative studies of geographic distribution for taxa of *Datura* have been published to date, and the

phytogeographic references available for this genus consist of generalized maps in taxonomic and floristic treatments (Satina and Avery, 1959; Bye, 1996; Luna-Cavazos et al., 2000). In this study we assess the distribution of the species of *Datura* in continental Mexico by means of clustering and ordination multivariate analyses.

Materials and methods

Data gathering. The analysis of the geographic distribution of *Datura* in Mexico was based on information obtained from plant specimens deposited in the following herbaria: ASU, CHAPA, CHP, CICY, D, ENCB, FCME, K, MEXU, MICH, MO, NMC, NY, POM, TEX UC, UNM, US, and XAL (acronyms after Holmgren et al., 1990). Additional *Datura* collections that were made by R. Bye and collaborators during their field studies which transected Mexico from Baja California to Yucatán were also included. From the 1 260 samples of *Datura*, 1 035 unique geographic coordinates were obtained; specimens without precise locality data or those from previously registered sites were not included in the study.

The quantitative analysis was based on procedures suggested by Birks (1987) and McLaughlin (1994). Mexico was divided into 239 1° x 1° sampling geographical units (or squares) based upon the maps (1:1 000 000 scale) in Cuanalo et al. (1989); over two-thirds of the country had at least one species registered employing this sampling unit size. Using the locality data from the herbarium specimens, the presence or absence of each species of *Datura* was recorded in each square. Afterwards, a database that noted the presence/ absence of species of *Datura* in squares was developed. In order to illustrate the geographic distribution of taxa and describe the regional diversity of the species of *Datura*, we generated maps using the program DIVA-GIS 5.2 (Hijmans et al., 2005). This same program was used to overlay these georeferenced points that were converted to decimals onto a map of the biogeographic regions as defined by Mexico's biodiversity agency (Comisión Nacional para el Conocimiento y Uso de la Biodiversidad; CONABIO, 1997).

Climatic, topographic and geographic data. Seven climatic variables and altitude derived from WorldClim Global Climate GIS database (30-s resolution) were analyzed using the program DIVA-GIS 5.2 (Hijmans et al., 2005). Within each geographic sampling unit with a register of *Datura*, the climatic data for all included georeferenced points were averaged in order to produce a value for each climatic variable of each square. A similar average of latitude and longitude was calculated in the case of the sample points within each square. The topographic and climatic data from WorldClim Global Climate GIS database

included: altitude (m.a.s.l.), annual mean temperature (°C), mean temperature of the wettest quarter (°C), mean temperature of the driest quarter (°C), mean temperature of the warmest quarter (°C), annual precipitation (mm), precipitation of the driest quarter (mm), and precipitation of the warmest quarter (mm). Using the variables of mean annual temperature and annual precipitation, the Aridity Index was calculated for each square (de Martonne, 1926). *Analysis of the geographic distribution of Datura.* One of the purposes of community analysis is to discover the similarities in biological diversity between sampling areas or sites (McCoy and Heck, 1987; McLaughlin and Bowers, 1990). Based on the above, the distribution data of 11 Mexican species of *Datura* were classified and arranged in order to answer 2 main questions: a), Are there similarities in the geographic distribution of the Mexican species of *Datura*? and b), Which environmental variables determine the similarities or differences in the geographic distribution of Mexican species of *Datura*?

Two complementary methods are used for the analysis of data of sites and species. Their purpose is to establish the similarities between plant communities in their response to environmental factors (Palmer, 1993): a) clustering, in which sites are grouped depending on their floristic similarity; and b) ordination, in which sites and/or species are placed along axes representing environmental gradients, that is an ordination through indirect gradient analysis (Palmer, 1993) and an analytical phase in order to explain the relationship between sites and species with environmental variables. To try to explain the geographic distribution of *Datura*, we used TWINSpan (Two Way Indicators Species Analysis) as a clustering method, and Detrended Correspondence Analysis (DCA) and Canonical Correspondence Analysis (CCA) as ordination methods through indirect and direct gradient analyses, respectively.

Data Analysis

Clustering. The distribution areas of the species of *Datura* were classified with the use of TWINSpan (Hill, 1979a) in order to detect general patterns in the biological data that will subsequently be related to differences in the environment (Gauch and Whittaker, 1981). Before assigning each division, TWINSpan uses an ordination obtained with Correspondence Analysis (CA), which results in a hierarchy of the division levels; major differences would be expected in the higher hierarchy divisions, possibly revealing greater environmental gradients.

Ordination

Detrended Correspondence Analysis (DCA). The Detrended Correspondence Analysis (Hill, 1979b; Hill and Gauch, 1980), devoid of tendency, was used to detect the main patterns of floristic variation in the distribution data. The optimum for each species was estimated using

reciprocal weighted averaging. The resulting eigenvalues for each axis were used as a measure of the relative importance of the ordination axes (ter Braak, 1987).

Canonical Correspondence Analysis (CCA). Repeatable general patterns of species' distribution may be the result of a few environmental variables that affect simultaneously all species (Gauch, 1982); therefore, one of the main objectives of this sort of biogeographical studies is to detect such environmental factors (Myklestad and Birks, 1993). Thus, a Canonical Correspondence Analysis was used to correlate geographical and climatic variables with the distribution patterns of species of *Datura*. Mathematical models and procedures supporting the CCA are described by ter Braak (1986, 1987). We used CCA to order the squares and species related to the environment where a matrix of squares and species was related to a matrix of squares and environmental variables (McCune and Grace, 2002). The purpose of this was to test if the species are related to the measured environmental variables and to indicate the relative importance of those variables in explaining distribution patterns of species of *Datura*. The environmental data matrix included the 165 squares and 11 environmental characters (table not shown, but available upon request from R. Bye), which were standardized by means of a logarithmic transformation (McCune and Mefford, 1999). From the correlation matrix we obtained the eigenvalues from the first 3 ordination axes which were in turn estimated with a regression of the canonic coefficients for the standardized values. The correlation species-environment was also obtained, as well as the percentage of accumulated variance for the relation species-environment. With CCA we intend to answer the following questions: 1) Which environmental variables are more important to explain the observed distribution patterns of *Datura*? and 2) Are the environmental variables significantly correlated to the species' data? Two kinds of analysis were used to answer this question: a) a Monte Carlo permutation test (99 permutations) was applied to each individual variable during the FORWARD selection of environmental variables (ter Braak, 1990) where the variables contributing the most to variance are probably the most important ones; b) a Monte Carlo permutation test from the individual axes was applied to determine if the canonical axes were greater than that at random, under the null hypothesis that there is no relationship between the floristic gradients detected for the species and the environmental variables measured.

The TWINSpan, DCA, and CCA analyses were made with the PC-ORD Program, Version 4, MjM Software Design, Oregon, USA (McCune and Mefford, 1999).

Results

General distribution and species richness. Species of *Datura* are distributed over a wide area of Mexico; 165 of the 239 squares (69%) had at least 1 species of *Datura*. There is no 1° x 1° area that includes the 11 taxa studied. The highest number of species recorded in a single geographic sampling unit is 7; this square is located at 18°-19° N and 99°-100° W, in the state of Guerrero in the Depresión del Balsas (DB) province. Two squares containing 6 species are located at coordinates 19°-20° N and 98°-99° W, on the border of the State of Mexico and Hidalgo in the Eje Volcánico (EV) province, and at 27°-28° N and 107°-108° W, in western Chihuahua in the Sierra Madre Occidental (SMOC) province. Five taxa were found at coordinates 18°-19° N and 98°-99° W, on the border of the states of Morelos and Puebla in the DB province, and at 24°-25° N and 107°-108° W, within the state of Sinaloa in the Sonorense province (SON) (Fig. 1). The most widely distributed species are *D. discolor*, *D. inoxia* and *D. stramonium*, which were recorded in 87, 69, and 55 squares, respectively. The most restricted taxa are *D. kymatocarpa* and *D. reburra*, located in 7 and 4 squares, respectively.

Numerical Analysis of *Datura*'s distribution

Clustering. The 165 sampling geographical units with *Datura* formed 14 groups according to TWINSpan (Fig. 2) that were associated with 19 biogeographic provinces. The first of the 2 TWINSpan branches at the first level (Fig. 2) separates the groups G1 to G7 (91 squares) from G8 to G14 (74 squares). The difference is related to altitude. In the

first division, the average altitude ranges from 52 m a.s.l. in G7 to 1 882.3 m a.s.l. in G3 with an average of 1 218.4 m a.s.l., while the altitude in the other division fluctuates between 191.5 m a.s.l. in G9 and 1 222.9 m a.s.l. in G13 with an average of 615.1 m a.s.l. (Table 1). Also, the aridity index influences the separation of these divisions where the set G1 to G7 has an average of 26.5, while the set G8 to G14 averages 16.7.

Within the first branch, G1 and G2 are characterized by *D. inoxia* and *D. quercifolia*, respectively, 2 taxa whose main distributions include central-northern Mexico (Fig. 3) and cover principally the Altiplano Norte (AN), the Altiplano Sur (AS), and the Sierra Madre Occidental (SMOC). G3 and G4 include *D. ceratocaula*, with the notable presence of *D. stramonium* (Fig. 4), elements located principally south of AS, the eastern part of SMOC, EV, and the extreme eastern DB. G3 is also represented by *D. inoxia* and *D. quercifolia* at the border of AS with EV. In the case of Groups 5, 6, and 7, the first 2 include squares mainly from central-southern Mexico, including southern Costa del Pacífico (CP), EV, DB, Sierra Madre del Sur (SMS), and isolated squares in other provinces such as extreme southern Golfo de México (GM), Yucatán (YUC), Petén (PET), and Los Altos de Chiapas (LACH) (Fig. 5). The most frequent species in the central and southern area is *D. stramonium* along with *D. pruinosa* and *D. kymatocarpa* to the south and *D. metel* further south in YUC and PET.

Within the second branch, groups G8, G9, and G10 include squares of northwestern Mexico, with the provinces of SON, north to CP, BC, and Del Cabo (DC),

AMT, annual mean temperature; MTWeQ, mean temperature of wettest quarter; MTDQ, mean temperature of driest quarter; MTWaQ, mean temperature of warmest quarter; AP, annual precipitation; PDQ, precipitation of driest quarter; PWQ, precipitation of wettest quarter; AI, aridity index.

as well as AN and SMOC, and SON, where *D. discolor* is the characteristic species and also *D. lanosa* and *D. reburra* stand out as 2 important elements. In addition, *D. discolor* is found in other provinces such as CP, Tamaulipas (TAM) and YUC (Fig. 6). G11 is a set of non-contiguous squares located south of latitude 22° on both coasts of Mexico, except for 1 isolated element in BC; this group is characterized by *D. stramonium* and *D. discolor* (Fig. 7). Geographic sampling units in groups G12, G13, and G14 are located in the provinces of BC, California (CA), and DC, as well as SON, where *D. wrightii* and *D. discolor* are the characteristic species (Fig. 8).

Shifting to the sub-branches at level 2, the set G1 to G4 is characterized by altitudes that average 1 630.4 m a.s.l.,

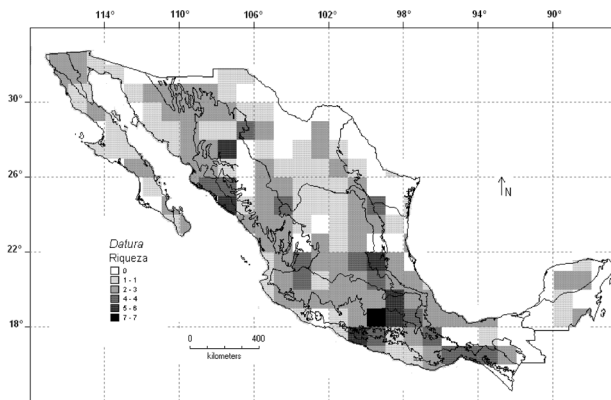

Figure 1. Species richness of the genus *Datura* in Mexico, as distributed in 239, 1° latitude × 1° longitude squares.

Figure 2. Classification of the squares and their corresponding biogeographic provinces based upon TWINSpan. N, number of squares in each division. CA, California; BC, Baja California; DC, Del Cabo; SON, Sonorens; SMOC, Sierra Madre Occidental; CP, Costa del Pacífico; AN, Altiplano Norte; AS, Altiplano Sur; EV, Eje Volcánico; DB, Depresión del Balsas; OAX, Oaxaca; TAM, Tamaulipeca; SMOR, Sierra Madre Oriental; GM, Golfo de México; YUC, Yucatán; PET, Petén; LACH, Los Altos de Chiapas; SOC, Soconusco; SMS, Sierra Madre del Sur.

range from 1 263.3 to 1 882.3 m a.s.l., and differ from all the other groups that average from 52 to 1 222.9 m a.s.l. (Fig. 2). Another important factor in these regions is the annual mean temperature, 18.2°C on average, compared to the remainder which average 21.7 °C (Table 1). The set G1 to G4 is characterized by species typical to the Altiplano Mexicano (AN and AS) as well as taxa from valleys and lower mountain areas of central Mexico, that is *D. innoxia*, *D. quercifolia*, and *D. ceratocaula*. Another characteristic set is that formed by G12 to G14, which includes geographic units basically from the Baja California Peninsula characterized by low precipitation levels, between 247 and 411.3 mm with an average of 306.9 mm, which are much less than those of the remaining sets with averages between 473.9 and 1335.4 mm annually. This precipitation pattern is further expressed in the low levels of the aridity index (8.3 to 14.2), typical of arid climates (de Martonne, 1926). The characteristic species of these regions are *D. wrightii* and *D. discolor*. The set G5 to G7 is differentiated by its geographic latitude, marked approximately on 20° N, and characterized by having the highest precipitation levels (1 134.5 mm on average). These levels result in higher aridity index values (33.1 on average and up to 50.5), typical of warm-sub-humid climates (de Martonne, 1926). The characteristic species are *D. stramonium* in central-southern Mexico (G5 and G6), and *D. metel* in the Yucatán Peninsula (G7). In regard to the set G8 to G11, the species are located on the Pacific coast and the Baja California Peninsula, with some squares on the coasts of the Gulf of Mexico and the Yucatán Peninsula.

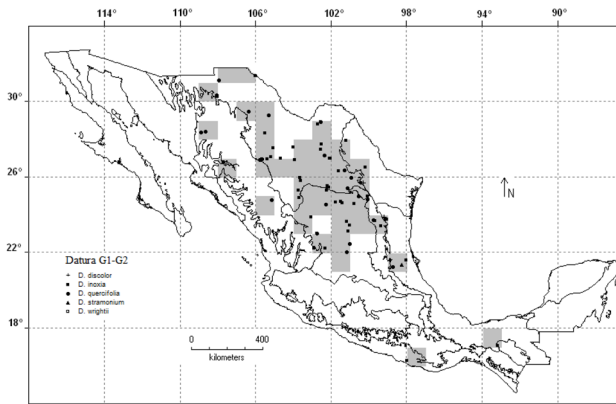

Figure 3. Characteristic species of *Datura* for groups 1 and 2. *D. discolor* (+), *D. inoxia* (■), *D. quercifolia* (●), *D. stramonium* (▲), *D. wrightii* (□).

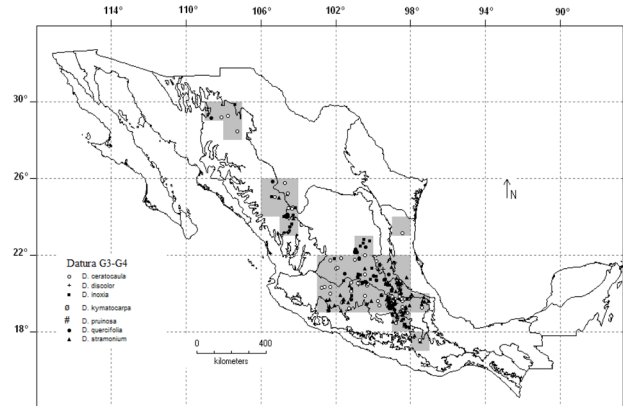

Figure 4. Characteristic species of *Datura* for groups 3 and 4. *D. ceratocaula* (o), *D. discolor* (+), *D. inoxia* (■), *D. kymatocarpa* (ø), *D. pruinosa* (#), *D. quercifolia* (●), *D. stramonium* (▲).

Altitude is the factor that differentiates these groups; the average altitude of this set is about 518.7 m a.s.l. while the others average 1 076 m a.s.l. The species appearing in all of these regions is *D. discolor* which, together with *D. lanosa*, characterizes G9, although its occurrence is very notable in G10 and G11.

Detrended Correspondence Analysis (DCA). Table 2 shows the eigenvalues of DCA's first 3 axes which represent important biological information. These axes account for 65% of the total variation. Given that axis 3 represents a small fraction of the accumulated variance (10.5%), only the first 2 axes will be considered in the interpretation of the data. The scores of the species and the squares in the first 2 axes of DCA are found in Figure 9. The geographic tendency of change of *Datura*'s species along the first DCA axis (variance of 28.5%), indicates that the species composition changes with longitude and humidity from northwest Mexico (right side on the axis) to central-northern and southern Mexico (middle and left side on the axis), which shows a tendency towards a northwestern-southeastern direction. On the second axis (variance of 26.2%), the tendency in species distribution follows a latitudinal gradient north to south in which the species whose primary distribution occurs in northern Mexico (i.e., *D. quercifolia*, *D. lanosa*, *D. reburra*, and *D. wrightii*) are located at the upper side of that axis, followed by *D. stramonium*. *D. pruinosa* and *D. ceratocaula*, taxa typical of central Mexico and, finally, *D. kymatocarpa* and *D. metel*, whose distribution area occurs in southern and south-southeastern Mexico. *Datura inoxia* and *D. discolor* are located in the central part of the gradient because of their wide distribution throughout Mexico. The differentiation tendencies are also evident in the squares where *Datura* is found (Fig. 9); axis 1 follows the northwest-southeast pattern mentioned above, which runs from the driest and lowest regions and includes mainly the squares from SON, BC, and

the north of CP (right side on axis 1), and continues to the east, south and southeast of the country, which are higher and wetter areas (left side on axis 1). Axis 2 is influenced by a latitudinal factor associated with humidity; thus, the north and northwestern areas of Mexico, with less precipitation (upper side on axis 2), typical of the AN and along with the already mentioned northwestern provinces of Mexico, differ from those areas of central Mexico (middle part on axis 2) where moister areas from EV and the southern part of SMO predominate. This tendency continues southward, to regions with a higher precipitation (approx. 1 000 mm) towards the south of the EV and SMS, ending on the far southeastern point of the Yucatán Peninsula (lower side in axis 2).

Canonical Correspondence Analysis (CCA). The first 3 eigenvalues and the percentage of accumulated variance of the data explained by the first 3 CCA axes are shown in Table 3. The first 2 axes ($\lambda_1 = 0.47$, $\lambda_2 = 0.31$) contain most of the biologically relevant information; therefore, the third axis will not be considered further. Table 4 depicts the intraset correlations of the environmental variables with axes 1 and 2, the *t*-values of canonical coefficients, and the variance explained by the corresponding variable.

The relative importance of environmental variables is shown on the biplot of Figure 10. The first axis is a gradient related to geographic longitude, precipitation of the driest quarter, altitude, mean temperature of the warmest quarter

Table 2. Eigenvalues and percent of accumulated variance of the first 3 axes of DCA

Axis	Eigenvalue	Cumulative Variance
1	0.68	28.5
2	0.38	54.7
3	0.28	65.2

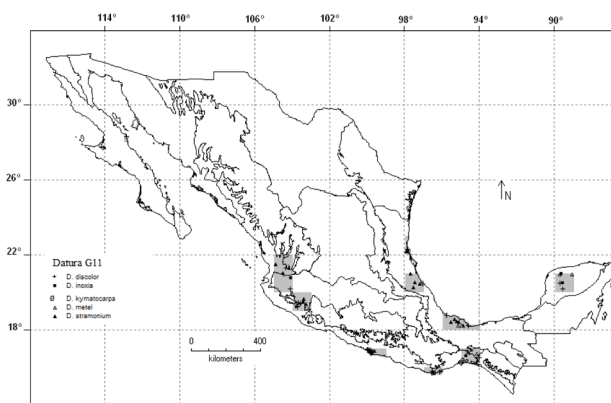

Figure 7. Characteristic species of *Datura* for group 11. *D. discolor* (+), *D. inoxia* (■), *D. kymatocarpa* (⊙), *D. metel* (△), *D. stramonium* (▲).

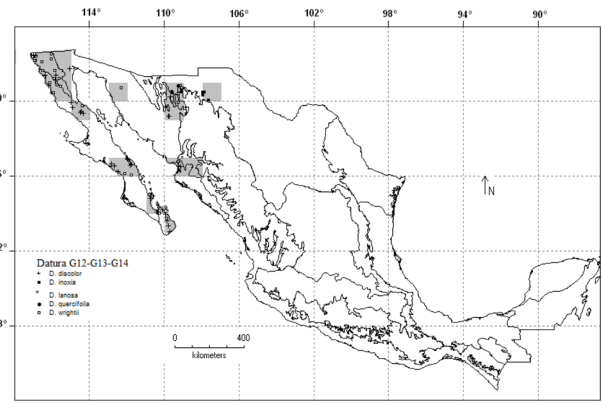

Figure 8. Characteristic species of *Datura* for groups 12, 13, and 14. *D. discolor* (+), *D. inoxia* (■), *D. quercifolia* (●), *D. lanosa* (★), *D. wrightii* (□).

and aridity index. The second axis is related to mean temperature of the driest quarter, annual mean temperature, and latitude as the most important variables. The correlation species-environment on axes 1 and 2 is of the order of 0.847 and 0.809, respectively, and is significant ($p < 0.01$).

The geographic patterns of species of *Datura* in relation to environmental variables can be inferred from the biplot of Figure 10. The positions of the species on the biplot closely resemble their locations in the DCA graph (Fig. 9). The species range from the distribution areas with the higher geographic longitude, lower altitudes, and low aridity index values (right side on first axis) to lower longitudes, higher altitude, and higher aridity indices (left side on the first axis). The pattern continues from areas with high mean temperatures, high precipitation, and lower latitude (upper side on second axis) to areas with low mean temperatures,

low precipitation, and higher latitude (lower side on second axis).

Discussion

General Distribution. In order to establish the origin of plant lineages, as well as their migration in space and time, we require fossil records. But when these resources are scarce, related research can include biosystematics and biogeography (Rzedowski, 1993). The descriptive analysis of the geographical distribution of species of *Datura* in Mexico permitted the visualization of the range of distribution of the studied species. The distribution maps allowed us: a), to identify the zones with the highest number of records of *Datura* species; b), to learn about the areas where there are no records of such species and

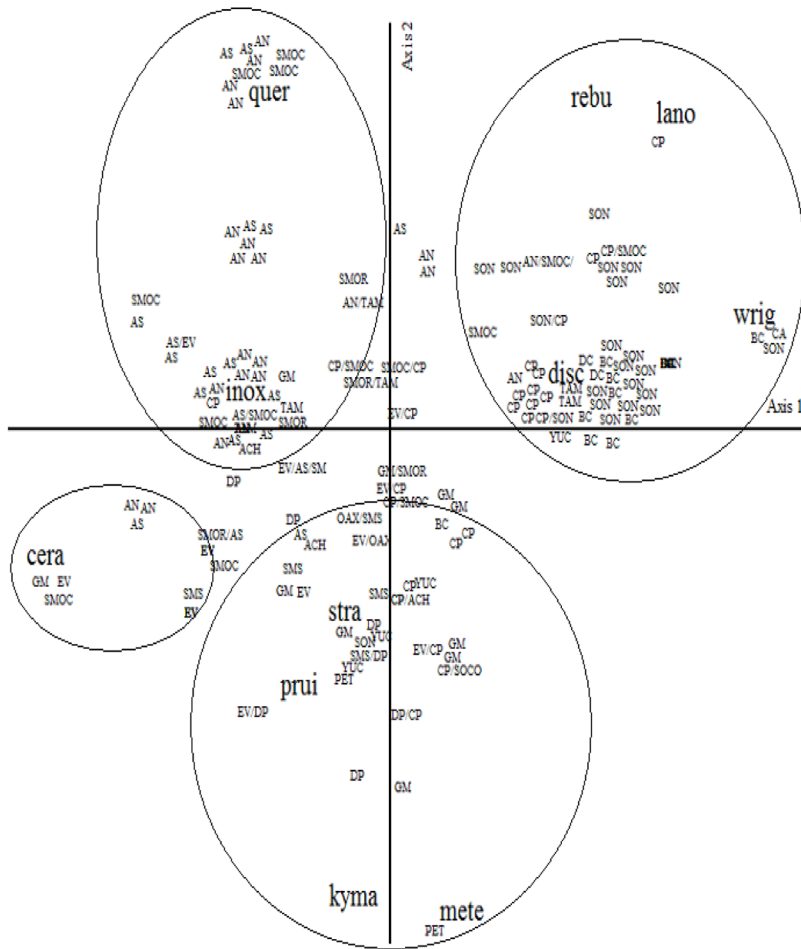

Figure 9. Ordination of squares and species based upon Detrended Correspondence Analysis for axes 1 and 2. The lower case letters correspond to *Datura* species and the upper case letters refer to the biogeographic province. cera, *D. ceratocaula*; disc, *D. discolor*; inox, *D. inoxia*; kyma, *D. kymatocarpa*; lanano, *D. lanosa*; mete, *D. metel*; prui, *D. pruinosa*; quer, *D. quercifolia*; rebu, *D. reburra*, stra, *D. stramonium*; wrig, *D. wrightii*. The codes for the biogeographic provinces are the same as those in Figure 2.

Table 3. Eigenvalues and percent of explained variance in the species data

	Axis 1	Axis 2	Axis 3
Eigenvalue	0.47	0.31	0.18
Variance in the species data			
% of explained variance	13.6	9.0	5.3
% of accumulated variance	13.6	22.6	27.9

which would be convenient to explore, and c), the areas of sympatry/allopatry of species. The extensive field work along with the consultation of herbarium specimens permitted the enrichment of the distributional information of the species in Mexico. In some cases, the presence of certain species in some localities was corroborated while in others, they were absent. In other cases, the records of species such as *D. reburra* with restricted distribution were enhanced and the inventories of those such as *D. discolor*;

D. stramonium, and *D. inoxia*, which have wide ranges but an uneven coverage, were complemented.

Relationship between areas. A higher degree of similarity between sites would imply that 1 or more factors allow the exchange of taxa between them (McCoy and Heck, 1987). The similarity between the AN and AS with SMOC (G1 and G2, Fig. 2), which is confirmed by the ordination (Figs. 9, 10), suggest that shared climatic conditions favor the exchange and dispersion of taxa

Figure 10. Ordination of squares and species based upon Canonical Correspondence Analysis for axes 1 and 2. The codes for the species and biogeographic provinces are the same as those for figure 17. ALT, altitude; LAT, latitude; LONG, longitude; AI, aridity index; AMT, annual mean temperature; PTA, precipitacion total annual; PDQ, precipitation of driest quarter; MTDQ, mean temperature of driest quarter; MTWQ, mean temperature of warmest quarter.

Table 4. Intraset correlations between 9 environmental variables and the ordination axes, *t*-values of the canonic coefficients

Variable	Intraset correlations		<i>t</i> -values		Std. Dev
	Axis 1	Axis 2	Axis 1	Axis 2	
Latitude	0.499	-0.731	-0.230	-0.556	0.084

AI	-0.563	0.425	0.575	-1.923	0.299

AMT, annual mean temperature; MTWeQ, mean temperature of wettest quarter; MTDQ, mean temperature of driest quarter; MTWaQ, mean temperature of warmest quarter; AP, annual precipitation; PDQ, precipitation of driest quarter; PWQ, precipitation of wettest quarter; AI, aridity index.

(e.g., *D. inoxia* and *D. quercifolia*, species typical of those provinces). This relationship between the Sierra Madre Occidental and the Mexican Plateau was also found in the geographic distribution of *Phaseolus* (Martínez, 1995). Another phylogeographic affinity is that of northwestern CP, SON, and BC provinces which share such species as *D. discolor*, *D. lanosa*, and *D. wrightii*. This distribution pattern between BC and SON provinces has also been noted for species of *Bursera* (Kohlmann and Sánchez, 1984) and *Phaseolus* (Martínez, 1995). According to Rzedowski (1978), similar climatic conditions between the physiographic region of Baja California and the Sonoran Plain – which have prevailed for approximately 10 000 years – contributed to the floristic affinity between both regions. A third example is that of SMOC, EV, and SMS as made evident by groups 4, 5, and 6 (Fig. 2). This pattern agrees with that found for *Phaseolus*, a genus for which this grouping of the SMOC, the western of EV, and the northwest section of SMS constitute a biological corridor between western and southern Mexico (Martínez, 1995).

Mexico's Pacific coast, with a predominance of tropical deciduous forests, is considered an important phylogeographical region with many endemic species, and a high species richness (Lott, 1993; Ceballos and García, 1995; Gentry, 1995). In the case of *Datura*, this diversity is reflected in the number of species found along this coast; some of them, such as *D. lanosa* and *D. reburra*, are native to the northern portion while others are distributed mainly in the southern portion, such as *D. metel* and *D. stramonium*. In the case of the widespread *D. discolor*, it is very common all along Mexico's Pacific coast from Baja California to Oaxaca.

Many species of *Datura* are found in Mexico's northwestern provinces, the most frequent being *D. discolor*, *D. lanosa*, *D. reburra*, and *D. wrightii*, and, to a lesser degree, *D. stramonium* and *D. quercifolia*. This area is an important center of diversity as well as an area of endemism due to the presence of geographically restricted species *D. lanosa* and *D. reburra* (Barclay, 1959; Bye et al., 1991). This region was considered to be important in the evolution of *Datura* by Lockwood (1973), who designated northwestern Mexico and the adjacent area of southwestern United States as the center of origin and evolution of *Datura*.

Relationship between species. Species assemblages are important in relation to their presence in the geographic units because, according to Jardine (1972), the level of correspondence between the groups obtained from the clustering in the geographic distribution allows us to propose the speciation and/or dispersion centers of the species. In the case of *Datura*, the ordination analysis showed a distribution pattern with a northwest-southeast

direction. Similar patterns have also been found in other plants, such as the wild species of *Phaseolus* in Mexico (Martínez, 1995).

The species' phylogeographic patterns provide indications of their biological relationships because morphologically and genetically related taxa tend to have similar distributions. This indicates that the intrinsic characteristics of the organisms, inherited from their ancestors, determine the ecological interactions that limit their geographical distribution (Brown et al., 1996). This is evident in the relation between *D. lanosa* and *D. wrightii*; these 2 taxa are morphologically similar (Luna et al., 2000), genetically related (Palomino et al., 1988; Jiao et al., 2002) and both are distributed in arid northwestern Mexico, even though *D. wrightii* is more common in the southwestern United States. On the other hand, comparable distribution patterns of taxonomically unrelated species may indicate the occupation of microhabitats within a broad ecological region suggesting their tolerance of certain climatic parameters that results in sympatry of species from different sections (Gómez-González et al., 2004); such as the case of *D. inoxia*, *D. quercifolia*, and *D. ceratocaula*, of sections *Dutra*, *Datura*, and *Ceratocaulis*, respectively (Satina and Avery, 1959; Hammer et al., 1983) that grow together on the Mexican Plateau.

Endemic species are the result of isolation due to geographical and ecological barriers (Gómez-González et al., 2004); this explanation is appropriate in the case of *D. kymatocarpa*, a species endemic to the DB province in Guerrero, an inland basin surrounded by the EV and SMS, a site where numerous endemic species from different taxonomic groups have been recorded (Kohlmann and Sánchez, 1984). Also, many endemic taxa in Mexico are concentrated mainly in regions with dry climatic conditions (Rzedowski, 1993); in the case of *Datura*, this applies to *D. lanosa* and *D. reburra*, native to the dry northwestern areas of Mexico. *Datura wrightii* is a similar case because, although it is not endemic to geopolitical Mexico, it falls within the northern portion of MegaMexico (Rzedowski, 1993) which includes areas with similar arid climate in adjacent southwestern United States.

Probably the wide distribution of some species of *Datura*, such as *D. stramonium*, is related to human migrations (Satina and Avery, 1959) and to environmental alterations associated with human activity. The same could be true for *D. inoxia*, a species frequently grown in home gardens for medicinal and ornamental purposes (Satina and Avery, 1959; Luna-Cavazos, 2001). *Datura metel* is cultivated as an ornamental plant, which would imply a wider distribution in Mexico, but its adaptation to regions with a warm-humid climate, such as the one prevailing in

southeastern Mexico, limits its distribution in other regions of the country.

Finally, the assemblages of groups based on floristic elements and floristic regions must be considered as reference points and not as definitive entities (Myklestad and Birks, 1993). With this research we propose that the distribution patterns uncovered in this study are a significant step forward in understanding the phytogeography of *Datura*.

Acknowledgments

We extend our gratitude to curators and staff of the herbaria that loaned the specimens and, in particular, to colleagues at COLO and MEXU. We acknowledge the bibliographic, field, and technical assistance of José Arellano, Jennifer Bain, Bruce Bartholomew, Francisco Basurto, Germán Bojórquez, Rafael Corral, Carlos Díaz, Francisco Félix, Oscar Ferrera, Raymundo García, Elia Herrera, Martín Hilerio, María Antonieta Isidro, Edelmira Linares, Rigoberto López, Gilberto Márquez, Miguel Ángel Martínez, Myrna Mendoza, Gustavo Morales, Eduardo Palacios, Guillermo Pichardo, Isaac Reyes, Lourdes Rico, Joel Rodríguez, Richard Spellenberg, Miguel Trejo, William A. Weber, and Hugh Wilson. Partial financial support for this work was provided by Comisión Nacional para el Conocimiento y Uso de la Biodiversidad (Project 088), International Cooperative Biodiversity Groups ("Bioactive agents from dryland biodiversity of Latin America" grant U01 TW 00316 from the National Institutes of Health, National Science Foundation, and USAID), and Universidad Nacional Autónoma de México. Consejo Nacional de Ciencia y Tecnología supported this work by providing a doctoral scholarship to ML.
